1. Introduction

In recent years, Machine Learning (ML) has been applied extensively to many problems, including customer journey optimization in marketing [27], particle identification in Physics [9], and mental health problems prediction in healthcare [26]. With their proven performance and increasing number of ML applications , several organizations are seeking third-party ML service providers to improve their operations, thus leading to the creation of a new business model — ML as a Service (MLaaS). As with other kinds of service, MLaaS requires a contract which is usually called a service level agreement (SLA) that sets the expectations and describes the delivered service to preserve the benefits of both stakeholders. However, the current SLA has yet to fulfill its preservation job because ML-specific attributes, such as data quality, inference accuracy, and explainability, have created new challenges. For instance, in Internet of Things (IoT) applications, many issues of the ML models have their root causes in the quality of data, which is impacted by many factors such as erroneous measurement, environmental noise, and discrete observations [19]. Moreover, because of the relationship between data quality and inference accuracy, ML models can produce false predictions when data quality problems exist, causing ML providers to be penalized based on the SLA. Another issue is that in MLaaS, the customers only submit the data and does not cooperate with the ML provider in the prediction task. Thus, from their perspective, ML models are considered to be a black box, which is insufficient in human life-related applications, such as e-health and autonomous vehicles, where uncertain decisions cannot be tolerated.

One approach to resolve these two challenges is increasing model explainability by interpreting the inference result to the customer [13]. However, explainability aspects of ML models have been researched mostly in the training task [19], making it unclear about the appropriate utilization and implementation of ML-specific attributes and constraints. As an approach to support ML-specific service

contracts, Linh et al.[28] proposed the QoA4ML framework which outlines the essential components of such contracts, the definition of ML attributes and constraints, and the guidance on the process to monitor and assess these elements. Although QoA4ML has created a foundation for robust ML monitoring, current implementation only focuses on general ML metrics such as the final confidence of the ensemble model. Consequently, because base models are challenging to monitor and explain with the current state of QoA4ML, they remain like a black box to both stakeholders. Such a level of explainability is not sufficient for some sophisticated applications, such as digital assistants, where a complex chain of models is employed. Additionally, with the increasing amount of research in autoscaler for the inference serving system [20] and automated ensemble [3], it demands a new technique to capture and visualize underlying inference graph to ensure dynamic and robust inference capabilities of ML solutions.

Recognizing above problem can be formalized as capturing data lineage, this thesis performs an analysis of data lineage monitoring and its implementation in edge environment. From that, the research proposes an approach to improve QoA4ML framework with data lineage, which can be combined with other techniques to improve the current MLaaS. This paper provides a prototype with QoA4ML as the foundation so that ML developer and provider can integrate it with their deployed service.

The rest of this paper is organized as follows. Section 2 discusses the background of the research, and section 3 explains data lineage implementation in the QoA4ML framework. Section 4 describes the experiment and its result, while section 5 concludes the research.

2. Background

This section presents the background on provenance for AI applications, ensemble ML, and its explainability challenge. Lastly, Section 2.3 discusses one standard for data model of provenance which is utilized in section 3.

2.1 Provenance and Data quality

The terms lineage, provenance, and traceability can be used interchangeably to refer to the process of constructing a final product, whether it is a digital file or a physical item [12]. Regarding lineage for the digital file, Wang et al [29] was the first paper to discuss those issues, which helped formally define provenance as “data source tagging” and “intermediate source tagging” problems [24, p. 5]. From its original interpretation, provenance has been applied in many domains such as scientific databases [30] [4] [21] [11], data warehouses [6] [7], and recently big data platforms [17] [10], and IoT [23]. In different applications, the types of lineages, their generating techniques, and main issue that they can answer are diverse [12]. For instance, there are four main provenance classes, i.e., provenance meta-data, information systems provenance, workflow provenance, and data provenance which are arranged from the most general to most specific process.

With the development of many AI applications, researchers have tried to incorporate provenance into the AI systems [2] by linking the input and output of the model, which can be a valuable source in interpreting the inference result. However, in this domain, provenance is commonly utilized in a rather general way, where entire algorithms or data transformations are merely represented by semantic relationships [14]. Consequently, while entire pipelines can be documented with provenance, the specific inner workings of individual models remain opaque.

Additionally, provenance is often considered when assessing data quality tasks,

e.g., evaluating integrity, trust, and accuracy. By analyzing provenance, the AI systems can detect errors in data generation and processing, which is valuable for IoT applications where data is uncertain, erroneous, and noisy [16].

2.2 Ensemble ML and its explainability challenges

Ensemble ML is a conventional technique that involves combining multiple models, which can reduce the variance of prediction, to improve the accuracy and robustness of predictions. This is achieved by utilzing multiple base models with different algorithms, hyperparameters, or subsets of features on the same input dataset, and then combining their results by applying various aggregation methods such as averaging, voting, or stacking to produce the final decision.

Such a technique has been shown to be highly effective in many applications including financial forecasting [25], image recognition [5], and natural language processing [8]. Then, as the demand for more precise forecasts and advanced applications, such as AI assistants or autonomous vehicles, increases, it requires a complex dataflow graph, usually represented by a direct acyclic graph (DAG), comprised of multiple base models that are interconnected and orchestrated to handle the input data sequentially or in parallel [20]. For each prediction request, the whole DAGs or only a subset of it can be involved, requiring ML providers to record the data flow of the inference task for further analysis and explanation. Additionally, in resource-constrained environments like the edge, ensemble selection rules can be applied so that only models that provide the best inference performance are utilized [3]. Although this approach can help resolve the challenges of high computation complexity, high resource occupation, and the moderate inference time of ensemble ML, it introduces uncertainty to the inference flow, making the data pipeline less transparent and explainable. Consequently, it is very challenging for current interpreting techniques to produce an explainable and transparent ML solutions without the data lineage of the ensemble model.

2.3 PROV Family

Researchers have proposed various models, languages, and tools to facilitate the documentation of provenance, including those tailored for AI/ML models [1]. However, it is still crucial to have a standard reusable ontology to capture provenance in heterogeneous environments, such as the web, for further development of provenance documentation. As an approach to resolve this problem, the PROV family of

PROV Concepts	Classes	Name
Entity	PROV-DM types	Entity
Activity		Activity
Agent		Agent
Generation	PROV-DM relations	WasGeneratedBy
Usage		Used
Communication		WasInformedBy
Derivation		WasDerivedFrom
Attribution		WasAttributedTo
Association		WasAssociatedWith
Delegation		ActedOnBehalfOf

Table 2.1. PROV-DM core concepts and types [18]

documents (PROV-OVERALL) was introduced by The World Wide Web Consortium (W3C) in 2013 [18]. In those documents, the most significant one is the PROV data model (PROV-DM) which provides a universal data model for provenance that can be applied to translate domain-specific and application-specific representations of provenance into a standardized format that can be shared between different systems. PROV-DM has ten core concepts which can be divided into types and relations like in Table 2.1. Then, as seen in Figure 2.1, PROV-DM describes the employment and production of *entities* by *activities*, which may be influenced in several manner by *agent*. In the following paragraphs, the proper definition and application of those data models will be discussed

Firstly, entities are the fundamental building blocks of the PROV-DM data model. They represent physical or digital objects involved in a process, such as a document, dataset, or prediction result. Entities can have fixed attributes that describe their characteristics, such as their size, quality, or creation time. Then, when the value of an attribute is adjusted, a new entity is produced and related to the previous version (“wasDerivedFrom”).

Secondly, activities are actions or processes that transform or manipulate entities. For instance, activities include data processing, predicting, and request serving. Activities can have attributes describing their properties, such as the start and end times of the task or the ML models employed to generate the prediction. Then, this data model can be “used” by entities as their inputs, and it can output a new entity which “wasGeneratedBy” the activities. Moreover, an activity can be informed by other activities with “wasInformedBy” relations.

Lastly, agents are entities that are responsible for carrying out activities (“wasAssociatedWith”), and when one activity is finished, an entity will be produced which

is attributed back to the agent (“wasAttributedTo”). Agents can be people, software tools, ML models, or other entities that can initiate or control activities. Additionally, an agent can “actedOnBehalfOf” other agents, describing the delegation relationship among them.

Section 3 will discuss the implementation of PROV-DM to capture data lineage of ensemble ML models.

Data lineage/provenance in AI systems: Data provenance is getting more attention when the demand for Explainable AI (XAI) increases. For instance, some researchers have proposed how provenance should be implemented: [15] introduced ‘Six Ws’ framework for provenance graph-based XAI; [22] combined abstraction and reasoning support offered by models with provenance graph which allows tracing the process of producing the current state.
